Abstract

We present a case of acute uterine inversion in the third stage of labor in which critical management decisions were facilitated by ultrasound imaging in the operating room. Identification of the ovary and adnexa pulled into the inclination of the inversion allowed successful diagnosis and guidance of uterine replacement.
Introduction

Although rare, uterine inversion is an obstetric complication that is associated with serious risks such as hemorrhage, sepsis and in some cases an emergency hysterectomy if it is not timely managed. Ultrasound imaging is used in fetal monitoring throughout pregnancy but it is not employed as frequently as a diagnostic tool during labor and delivery. Clinical assessment alone may not be sufficient to diagnose and replace an inverted uterus.

Case Report

The patient was a 26-year-old gravida 3 para 2 with an uncomplicated prenatal course who presented to Labor and Delivery at 40 weeks gestation at 6 cm dilated in active labor. She had two previous normal spontaneous vaginal deliveries. The patient’s surgical history was significant only for an abdominal hernia repair. She had no other history of uterine procedures. Artificial rupture of membranes was performed and progressed normally to complete dilation. She had an 18-minute second stage of labor followed by a spontaneous vaginal delivery of a 3475g male infant. A true knot was noted in the umbilical cord. The third stage of labor was managed expectedly, without spontaneous expulsion of the placenta within 30 minutes. A manual extraction of the placenta was attempted. As the placenta was delivered, clinical examination identified a uterine inversion. An attempt was immediately made to replace the uterus within the abdominal cavity using manual pressure on the inverted fundus. Clinically, it was felt that the replacement was successful; however, she was taken to the operating room for an
exam under anesthesia which confirmed that the uterus was only partially replaced. Nitric
oxide was administered to assist the further replacement of the uterus which was initially
believed to be successful. An ultrasound examination was performed in the operating
room (GE Pro LOGIQ 200, Proseries, Milwaulkee, WI). The sagittal plane just lateral to
the midline showed what appeared to be an essentially normal configuration of the uterus
with a midline stripe. (Figure 1)

However, when the transducer was moved to the midline, an indentation of the
cephalad portion of the uterus was identified with a structure on top that seemed to be
coming from the indentation. (Figure 2) This was identified as the left ovary with the
hyperechoic proximal adnexal structures pulled with the inverted uterus towards the
vagina. The image of the ovary at the indentation orifice, simulated the appearance of a
“stuffed olive.” Inhaled nitric oxide was given again, and using ultrasound guidance, the
uterus was reverted to a normal uterine position with post-procedure confirmation.
Uterotonics were administered.

The patient tolerated the procedures well; however, due to significant bleeding
and postoperative hemoglobin of 6.4, she was transfused postpartum. She was discharged
to home on day three in good condition.

Discussion:

Uterine inversion is considered an obstetric emergency, and is associated with
significant maternal morbidity including maternal hemorrhage, sepsis, need for
laparotomy, and hysterectomy. Mortality is a risk, especially in resource poor delivery
situations, although death is rare in the recent literature. 1,2 Reported rates vary from
1:1,200 to 1:57,393 births which probably reflects wide variations in management of the third stage of labor.\textsuperscript{1} Management is based upon timely recognition of the inversion with immediate attempts to reposition the uterus. While largely successful if performed immediately, some uterine inversions can be difficult to correct. Availability of ultrasound in most labor and delivery suites has given an opportunity to use imaging to guide clinical management. Although the ultrasound equipment used on a Labor and Delivery is often less sophisticated than that used for intensive prenatal diagnosis programs, capture and recognition of obstetric abnormalities in the acute care setting is still possible and desirable.\textsuperscript{3}

The ultrasound appearance of acute postpartum uterine inversion was first described in 1985, with a total of eight cases having images including the present case.\textsuperscript{4-10} (Table 1) Of these, two (25\%) showed ultrasound features of uterine inversion in the early postpartum period, but the significance of the images was not initially recognized.\textsuperscript{4,8} In four (50\%) of the cases, a uterine inversion was not immediately recognized after delivery with delays in diagnosis ranging from 20 hours to 8 weeks.\textsuperscript{4,6,8,10} One case (12.5\%), had an immediate uterine replacement performed, but returned for a “routine” post partum visit where a chronic inversion was diagnosed both clinically and with ultrasound.\textsuperscript{9} Our case could have followed a similar course, if ultrasound had not been used to confirm that the initial attempts at the inversion correction were not successful.

Importantly, of the five cases requiring laparotomy, four (80\%) were associated with delayed diagnoses.\textsuperscript{4,5,8-10} Given that morbidity increases proportionately to the amount of time the diagnosis is delayed, prompt recognition and treatment of the condition is critical.
Ultrasound in this case was helpful in clarifying an incomplete correction of the inversion, which assisted in timely and successful attempts to complete the uterine replacement, thereby avoiding delay and further complications. In addition, we were able to identify clearly an ultrasound feature of uterine inversion, which would be the ovary positioned at the uterine inversion indentation in a sagittal plane giving the appearance of a “stuffed olive.” Based on our experience with this case and reviewing the literature, we would suggest that ultrasound be used for all clinical suspected cases of uterine inversion to confirm appropriate replacement of the uterus to its normal anatomic position. The ultrasound examination should include sagittal images across the entire uterus, since images that are not exactly midline may be misleading and could give the false impression of normal anatomic position of the uterus. If identified, even partial uterine inversion should be corrected due to the increased risk for the development of a chronic uterine inversion requiring laparotomy for treatment.
