Case Presentation:

Patient: 71 year-old Caucasian male.

History of Present Illness: Our patient presented with a one-year history of a nodule on the vertex of the scalp. The lesion had become soft and tender during the week prior to presentation. He admitted to headaches and a buzzing sound in his head. He denied all other neurologic symptoms. The patient was given amoxicillin from a primary care physician and was referred to us for excision of a presumed inflamed cyst. Upon superficial incision, there was more bleeding than would be expected for a scalp, and the procedure was immediately discontinued. Hemostasis was obtained and the patient was sent for an ultrasound of the lesion. Ultrasound demonstrated the lesion to be vascular in nature, and cerebral angiogram demonstrated a, “recurrent dural arteriovenous fistula of the superior sagittal sinus with multifocal supply,” which connected with this scalp nodule. The patient was treated by interventional neuroradiology with intravascular embolization, which resulted in complete resolution of the scalp nodule.

Medical History/Surgical History: Intracranial arteriovenous fistula treated in 2013, two substantial falls in childhood with head trauma and loss of consciousness, essential hypertension, aortic aneurysm

Medications: Amlodipine, lisinopril, amoxicillin, multi-vitamin, grape seed extract

Physical Examination: The patient had a 2 cm pink, somewhat rubbery, subcutaneous, non-mobile nodule on the vertex of the scalp (Figure 1).

Studies: An ultrasound performed demonstrated a “small hypoechoic nodule measuring up to 0.5 cm containing a tangle of vessels in the subcutaneous soft tissue corresponding to the palpable abnormality.” A cerebral angiogram demonstrated a “recurrent dural arteriovenous fistula of the superior sagittal sinus with multifocal supply,” which connected with this scalp nodule (Figure 2).

Discussion:

Scalp arteriovenous fistulas (S-AFVs) are characterized by abnormal connections between supplying arteries and draining veins in the subcutaneous plane of the scalp. The veins of a S-AVF undergo progressive aneurysmal dilatation as a result of abnormal hemodynamics. S-AFVs may present as a progressively enlarging pulsating mass on the scalp. Associated symptoms may include headache, local pain, bruits, tinnitus, and thrill. Hemorrhage and necrosis are less commonly associated.

S-AFVs may occur with or without intracranial communication. Spontaneous S-AFVs with intracranial communication are uncommon and their etiology is unclear. Spontaneous S-AFVs may form as congenital malformations or may be idiopathic. Most patients remain asymptomatic until puberty and typically seek medical attention after the second decade. Factors increasing the circulation through the S-AVF such as trauma, pregnancy, hormonal changes, endocrine stimulation, and inflammation prompt the development of symptoms.

S-AFVs may also be caused by trauma. S-AFVs without intracranial communication have been reported following hair transplantation. S-AFVs with intracranial communication may develop months to years after skull fracture or craniotomy. True spontaneous S-AFVs are difficult to differentiate from traumatic S-AFVs other than by history alone.

There are three proposed hypotheses for the development of spontaneous S-AFVs. The first is the persistence of primitive arteriovenous communication and capillary agenesis. The second suggests that S-AFVs originate from vascular hamartomas. The third is the formation of a fistula at the site of arteriovenous crossing.

The diagnosis of a S-AVF is confirmed with imaging studies. A doppler ultrasound will help to initially detect that a lesion is vascular in nature. Intra-arterial digital subtraction angiography is the gold standard imaging technique and is necessary to delineate the feeding arteries and the draining channels, as well as possible communication with intracranial vasculature.

There is controversy regarding the appropriate treatment of S-AFVs. The prognosis for S-AFVs is extremely variable and the decision to treat is based upon the patient’s symptoms and risk of exsanguinating hemorrhage. Neurosurgical approaches to the management of S-AFVs include ligation of the feeding arteries, surgical resection, electrothrombosis, and embolization. Endovascular intervention is increasingly being used as a primary treatment or as a pre-operative adjunct to surgery. In cases with intracranial communication, the intracranial component is treated first.

We report this case to emphasize the importance of keeping S-AFVs on the dermatologic differential diagnosis of a scalp mass. We recommend taking a thorough history, inquiring about the associated S-AVF symptoms, palpating suspicious scalp masses for bruits, and appropriate imaging if indicated. S-AFVs should be referred to neurosurgery or interventional neuroradiology for evaluation and possible treatment.
